Abstract In this paper, the procedures to test global search algorithms applied to space trajectory design problems are discussed. Furthermore, a number of performance indexes that can be used to evaluate the effectiveness of the tested algorithms are presented. The performance indexes are then compared and the actual significance of each one of them is highlighted. Three global optimization algorithms are tested on three typical space trajectory design problems.

Keywords: Global optimization, Stochastic optimization, Space trajectory design.

1. Introduction

In the last decade, many authors have used global optimization techniques to find optimal solutions to space trajectory design problems. Many different methods have been proposed and tested on a variety of cases. From pure Genetic Algorithms (GAs) [6, 4, 8, 1] to Evolutionary Strategies (ESs) (such as Differential Evolution, DE) [11] to hybrid methods [12], the general intent is to improve over the pure grid or enumerative search. Sometimes, the actual advantage of using a global method is difficult to appreciate, in particular when stochastic based techniques are used. In fact, if, on one hand, a stochastic search provides a non-zero probability to find an optimal solution even with a small number of
function evaluations, on the other hand, the repeatability of the result and therefore the reliability of the method can be questionable. The first actual assessment of the suitability of global optimization method to the solution of space trajectory design problems can be found in two studies by the University of Reading [5] and by the University of Glasgow [10]. One of the interesting outcomes of both studies was that DE performed particularly well on most of the problems, compared to other methods. In both studies, the indexes of performance for stochastic methods were: the average value of the best solution found for each run over a number of independent runs, the corresponding variance and the best value from all the runs. For deterministic methods, the index of performance was the best value for a given number of function evaluations. In this paper, we propose a testing methodology for global optimization methods addressing specifically black-box problems in space trajectory design. In particular, we focus our attention on stochastic based approaches. The paper discusses the actual significance of a number of performance indexes and proposes an approach to test a global optimization algorithm.

2. Testing Procedure

In this section we describe a testing procedure that can be used to derive the performance indexes described in the next section.

If we call $A$ a generic solution algorithm and $p$ a generic problem we can define a convergence test as in Algorithm 1.

**Algorithm 1 Convergence Test**

1. set the max number of function evaluations for $A$ equal to $N$
2. apply $A$ to $p$ for $n$ times
3. for all $i \in [1, \ldots, n]$ do $\phi(N, i) = \min f(A(N), p, i)$
4. end for
5. compute: $\phi_{\min}(N) = \min_{i \in [1, \ldots, n]} \phi(N, i), \ \phi_{\max}(N) = \max_{i \in [1, \ldots, n]} \phi(N, i)$

Now if the algorithm $A$ is convergent, when the number of function evaluations $N$ goes to infinity the two functions $\phi_{\min}$ and $\phi_{\max}$ converge to the same value, the global minimizer. Note that not all the algorithms have this property and depending on the complexity of the problem the value of $N$ can be finite or not. The value of $N$ therefore gives a measure of the complexity of the problem or equivalently the effort required to a given algorithm to solve the problem under investigation. If Algorithm 1 is applied to a generic problem with a generic algorithm we can have three cases:

1. $\exists N \in \mathbb{N}$ such that $\phi_{\min} = \phi_{\max}$
2.3 N \in \mathbb{N} such that \( \phi_{\min} = \phi_{\max} = f_{\text{global}} \)

3. \exists N \in \mathbb{N} such that \( \phi_{\min} = \phi_{\max} = f_{\text{global}} \)

If case 3 is true then we can have an exact measure of the complexity of the problem and of the ability of an algorithm \( A \) to solve problem \( p \). However, the procedure in Algorithm 1 can be unpractical since, though finite, the number \( N \) could be very large. Moreover, it could be the case that we are not interested in finding the global minimum all the times we run \( A \) on \( p \). In fact the value of \( N \) for which case 3 is true implies that by applying \( A \) to \( p \) we find always the global minimum. Therefore, we can look at the performance of an algorithm \( A \) applied to \( p \) for a given \( N \). Now, let us define the quantity \( \delta_f = \| f_{\text{global}} - f(x) \| \) where \( f_{\text{global}} = f(x_{\text{global}}) \) and \( \| \cdot \| \) is the Euclidean norm. If the global minimum is not known a priori, we can compute \( \delta_f \) by means of \( x_{\text{best}} \) and \( f_{\text{best}} = f(x_{\text{best}}) \) which refer to the best known result \( \delta_f = \| f_{\text{best}} - f(x) \| \)

We can now define the procedure, summarized in Algorithm 2.

**Algorithm 2 Convergence to the global optimum**

1. set the max number of function evaluations for \( A \) equal to \( N \)
2. apply \( A \) to \( p \) for \( n \) times
3. set \( j = 0 \)
4. for all \( i \in [1, \ldots, n] \) do
5. \( \phi(N, i) = \min f(A(N), p, i) \)
6. compute \( \delta_f \)
7. if \( (\delta_f < \text{tol}_f) \) then \( j = j + 1 \)
8. end if
9. end for

A key point is properly setting the value of \( n \), because a value of \( n \) too small would correspond to an insufficient number of samples to have a proper statistics. The value of the tolerance parameter \( \text{tol}_f \) depends on the size of the basin of attraction of the minima, but they have not to be necessarily set a priori and are less crucial for the analysis. Note that, in the case of multiple minima with equal \( f \) also the distance \( \| x - x_{\text{global}} \| \) would be relevant, however in the following we are only interested in the value of the merit function.

### 2.1 Performance Indexes

Now that the testing procedure is defined we can define the performance indexes. For a stochastic based algorithm different performance indexes can be defined. In the following we will discuss about the sig-
nificance of some of them keeping in mind the practical use of a global optimization, or global search, algorithm in space trajectory design.

The current practice is mainly focused on the evaluation of best value, mean and variance values of the best solutions found on \( n \) runs. An algorithm is considered as better performing as the obtained mean value is closer to the global optimum and a small variance is considered as a suggestion of robustness. This approach, however, does not consider at least two main issues: a) very rarely the distribution of best values can be approximated with a gaussian distribution and b) from a practical standpoint, usually, when we use an algorithm to solve a global optimization problem, we are not interested in mean values, which could be faraway from the optimum.

An alternative index that can be used to assess the effectiveness of a stochastic algorithm is the success rate, which is related to the \( j \) value in algorithm 2, being \( Sp = j/n \). Considering the success as the referring index for a comparative assessment implies two main advantages. First, it gives an immediate and unique indication of the algorithm effectiveness and, second, the success rate can be represented with a binomial probability density function (PDF), independently of the number of function evaluations, the problem and the type of optimization algorithm. This means that we can derive the minimum number of runs, \( n \), that are required to have a given level of confidence in the correctness of the estimated success rate. For a binomial distribution, it is common use to assume both the normal approximation for the sample proportion \( p \) of successes, i.e. \( p \sim N\{\theta, \theta(1-\theta)/n\} \), and the requirement that \( Pr[|p-\theta| \leq \alpha \theta] \) should be at least \( 1 - \alpha \) [2]. This leads to expression in eq. 1 and to the conservative rule in eq. 2, obtained if \( \theta = 0.5 \)

\[
\frac{n \geq \theta(1-\theta)\chi^2_{(1),\alpha}/d^2}{n \geq 0.25\chi^2_{(1),\alpha}/d^2}
\]

For our tests we considered \( n = 200 \), which should guarantee an error \( \leq 0.05 \) with a 95% confidence.

3. Problem Description

Three different test-cases, with different difficulty levels, are considered. In all of these cases the objective will be to minimize the variation of the velocity of the spacecraft due to a propelled maneuver, \( \Delta v \). Minimizing the \( \Delta v \) means minimizing the propellant mass required to perform the maneuver, since propellant mass increases exponentially with \( \Delta v \).
A simple, but already significant, application is to find the best launch date and time of flight to transfer a spacecraft from Earth to the asteroid Apophis. The transfer is computed as the solution of a Lambert’s problem [3], therefore the design variables are the departure date from the first celestial body, $t_0$ and the flight time $T_1$ from the first to the second body. The launch date from the Earth has been taken in the interval $[3653, 10958]$ (number of elapsed days since January 1st 2000, MJD2000), while the time of flight has been taken in the interval $[50, 900]$ days. The known best solution is $f_{\text{best}}=4.3745658$ km/s.

The second test-case consists of a transfer from Earth to Mars with the aid of a gravity assist manoeuvre at Venus to alter the path and the speed of the spacecraft. The mission is implemented as a Lambert’s arc from the Earth to Venus, a Venus-Mars arc with a midcourse deep-space manoeuvre and a gravity assist maneuver at Venus. The problem has dimension 6, $t_0$ [d, MJD2000] $[3650, 3650+365.25\times15]$, $T_1$ [d] $[50, 400]$, $\gamma_1$ [rad] $[-\pi, \pi]$, $r_{p,1}$ [1, 5], $\alpha_2$ [0.01, 0.9], $T_2$ [d] $[50, 700]$, where $\gamma_1$, $r_{p,1}$ and $\alpha_2$ are related to the gravity assist maneuver and are the angle of the hyperbola plane, the radius of the pericentre of the hyperbola normalized with the radius of the planet and the fraction of time of flight before the deep space manoeuvre, respectively. The best known solution is $f_{\text{best}}=2.9811$ km/s.

The third test is a multi gravity assist trajectory from the Earth to Saturn following the sequence Earth-Venus-Venus-Earth-Jupiter-Saturn (EVVEJS). Gravity assist maneuvers have been modeled through a linked-conic approximation with powered maneuvers, i.e., the mismatch in the outgoing velocity is compensated through a $\Delta v$ maneuver at the GA planet. No deep-space maneuvers are possible and each planet-to-planet transfer is computed as the solution of a Lambert’s problem. The objective function is given in [9] and also in this case the dimensionality of the problem is 6, $t_0$ [d, MJD2000] $[-1000, 0]$, $T_1$ [d] $[30, 400]$, $T_2$ [d] $[100, 470]$, $T_3$ [d] $[30, 400]$, $T_4$ [d] $[400, 2000]$, $T_5$ [d] $[1000, 6000]$. The best known solution is $f_{\text{best}}=4.9307$ km/s.

Due to format requirements, it is not possible to exhaustively describe the problems, but they are freely available on request as black-box executables.

4. Used Algorithms

We tested three global search algorithms belonging to the class of stochastic algorithms. More precisely, one belongs to the class of ESs, one to the class of GAs and one to the class of agent-based algorithms.
We considered 6 different settings for the DE, resulting from combining 3 sets of populations, \([5d, 10d, 20d]\), where \(d\) is the dimensionality of the problem, 2 strategies, 6 (DE, best, 1, bin) and 7 (DE, rand, 1, bin) [7], and single values of stepsize and crossover probability, \(F = 0.75\) and \(CR = 0.8\) respectively, on the basis of common use.

For the Particle Swarm Optimization (PSO) algorithm, 9 different settings were considered, resulting from the combination of 3 sets of population, again \([5d, 10d, 20d]\), 3 values for the maximum velocity bound, \(V_{\text{max}} \in [0.5, 0.7, 0.9]\), and single values for weights, \(C_1 = 1\) and \(C_2 = 2\).

Regarding the GA application, only the influence of the population size was considered (\([100, 200, 400]\) for the bi-impulse test case and \([200, 400, 600]\) for the other two cases), with single values for crossover and mutation probability, \(C_r = 1\) and \(M_p = 1/d\).

The algorithms operated on normalized (\([0,1]\)) search spaces.

5. Comparison Among Performance Indexes

The results of the tests are summarized in table 1 and 2, where success probability and besta value, mean and variance of best results are given for each of 18 (set)solvers. For both EA and EVM cases, success probability allows a fair classification and gives a clear indication of the best performing algorithms. Algorithms 5 and 6, DE with strategy 7 and 10\(d\) and 20\(d\), respectively, perform undoubtedly much better than the others and GAs (algorithms 16, 17 and 18) appear to be the worst performing ones. The algorithm 4 wins a bronze medal, but if we can be confident on its third position for the EVM problem, we cannot have the same level of confidence regarding the third position for EA, because of the proximity of other algorithms. Actually, due to the binomial nature of the success and the adopted sample size, it is not possible to fairly discriminate between algorithms, for which the success distance is smaller than the expected error. Therefore, algorithm 4 has to be considered at the same level of 11, 13 (PSO, \([10d, V_{\text{max}}=0.7]\) and \([10d/2, V_{\text{max}}=0.9]\), respectively) and other PSO settings. For the same reasons, we can say that, among the PSO settings, 11 and 13 perform better than 8 (\([10d, V_{\text{max}}=0.5]\)), but the remaining algorithms work at the same level.

An analogous vagueness condition shows for most of the algorithms when applied to EVM and almost all of them when applied to EVVEJS, for which, in particular, all of algorithms appear practically unsuccessful, because, even if the success probability cannot be considered really 0, due to the error margin, it is \(\leq 0.12\), according to the expected error.

For cases when the success probability cannot give practically useful information to classify the algorithms, the user could be tempted to use
Table 1. Success for the 18 algorithms on the three test-cases. To compute the success, following tol values were used: 0.001 for EA, $3 - f_{\text{best}}$ for EVM and $5 - f_{\text{best}}$ for EVVEJS.

mean and variance values, but this practice is strongly heedless. Since, how anticipated in section 2.1 and confirmed by tests (see figure 1), the PDF of the best values is not a gaussian and, moreover, changes during the process, mean and variance values are not enough to understand the algorithm behaviour and we cannot say anything about their exactness.

Even if we suppose mean and variance are correct (in some way), looking at these two values can bring to incorrect conclusions. For instance, if we consider the values for the algorithms 14 (PSO, $[10d, V_{\text{max}}=0.9]$)
and 17 (GA, pop=400), applied to EVM, we could conclude that 17 performs better than 14, because of a smaller mean value and a smaller variance (regarded as an index of robusteness). But, if we are interested in global optimal solutions, 17 is noticeably better: it is able to find the global solution, even if it is less robust and gets stuck many times in a far basin (see figure 2).

In order to solve an uncertainty condition, for instance when the success probability appears uniformly null, relaxing the tol\(f\) value could be useful. Focusing on the EVVEJS case, there is no way to correctly discriminate among the algorithms on the basis of data in table 1, but if the success threshold is raised from 5 to 5.3, then a superior performance of GAs is revealed. Likely, this behaviour is due to the mutation search operator, which in this complex case helps the GAs to get near the global solution, without allowing to find the proper one.

As previously stated, for all the tests, 200 runs were performed in order to maintain the error on the success probability within a predefined margin. The extreme importance of the sample size appears evident when we look at figure 3, where the variation of the success probability is shown as function of \(n\). For \(n \leq 50\), the success is extremely oscillating and the confidence on the obtained value should be considered poor.

---

**Figure 1.** Variation of the PDF for best solutions with \(N\) for the algorithm 6 applied to EA test-case; discrete, incorrect gaussian approximation (dashed) and kernel based approximation (continuous) are shown.
6. Conclusions

The work focuses on the testing procedures for the application of global optimization algorithms to space trajectory design and tries to set the basis for a standard and consistent procedure. The current testing practice and the currently used performance indices are criticized and a preliminary testing/analysis procedure is proposed and the probability of success is indicated as the most useful index, when performance of different algorithms are to be compared. Moreover, the binomial nature of this index allows to link the number of performed runs to the expected error on the success itself, while it is not possible to have the same statistical consistency when mean and variance values are utilized, because of the unknown nature of the PDF for the best values. In general, it should be stressed that if the comparative tests have to be reliable, the number of runs cannot be lower than a threshold depending on the nature of the considered indices.
In the future, the testing procedure will be improved by considering also the heuristics costs and the link between the performance of some heuristics and the main structures of the test-cases
