Abstract

Introduction: There are concerns with rising rates of antimicrobial resistance (AMR) across countries with appreciable impact on morbidity, mortality and costs. Amongst low- and middle-income countries, a key driver of AMR is the excessive use of antibiotics in ambulatory care, with a critical area being the appreciable selling of antibiotics without a prescription often driven by patient demand and limited knowledge. There is currently conflicting evidence in South Africa regarding this practice. Consequently, there is a need to explore these critical issues amongst patients, especially in more rural areas of South Africa. A pilot study was undertaken to address this. Methods: A two-step descriptive approach was undertaken. This involved two questionnaires amongst patients exiting chain and independent community pharmacies followed by cognitive interviews. Results: Overall, 21 patients were approached for an interview, including 11 for Part 1 of the questionnaire with 3 declining, and 10 for Part 2, with 2 declining. Subsequently 8 patients completed each part of the questionnaire. On average, it took 2 min 13 s to complete both parts. 3 of the 5 patients being dispensed an antibiotic were dispensed one without a prescription, with all 3 patients exiting from independent pharmacies. Key reasons for self-purchasing included money and convenience. There was mixed knowledge regarding antibiotics and AMR amongst the 8 patients interviewed with Part 2. Overall, there was a satisfactory understanding of the Part 1 questions, although some modifications were suggested. Some participants had difficulty with fully understanding the questions in Part 2, with a number of suggestions made to improve this for the main study. Conclusion: There were concerns with the extent of purchasing antibiotics without a prescription in this pilot study as well as the knowledge of patients regarding antibiotics and AMR. Both areas need addressing and will be explored further in the main study.

Keywords: Antibiotics, antimicrobial resistance, patients, pharmacies, purchasing antibiotics, South Africa

INTRODUCTION

The global rise in antimicrobial resistance (AMR) has appreciably increased morbidity, mortality and costs, with the greatest burden from AMR currently seen in sub-Saharan Africa.[1-4] As a result, there are now multiple national and global initiatives to reduce AMR. These include the World Health Organization with its Global Action Plan alongside National Action Plans (NAPs) to reduce AMR.[5-8] A key focus...
as part of the NAPs for health authorities and governments across low- and middle-income countries (LMICs), including African countries, is to improve the prescribing and dispensing of antibiotics in ambulatory care. This is important because ambulatory care currently accounts for 90%-95% of total human antibiotic consumption in LMICs. Within ambulatory care in LMICs, including amongst African countries, a key area to address is currently high rates of antibiotics being purchased without a prescription, often for self-limiting conditions including acute respiratory infections (ARIs), driving up AMR.

We are aware of the critical role that patients play across Africa in influencing the prescribing and dispensing of antibiotics, especially for essentially self-limiting conditions. Inappropriate pressure on pharmacists or their assistants to obtain antibiotics, including being dispensed without a prescription, is often fuelled by a lack of knowledge amongst patients about antibiotics and AMR. Alongside this, patients’ previous experience with antibiotics for the successful treatment of their infectious diseases, including often for self-limiting conditions, enhances this pressure.

A number of key factors have been identified fuelling the purchasing of antibiotics without a prescription across Africa. These include issues of affordability, pressure from patients, limited enforcement of regulations prohibiting the purchasing of antibiotics without a prescription, lack of knowledge regarding antibiotics and AMR amongst patients as well as prior experience with antibiotics to successfully treat previous infections.

Across countries, there are concerns with the knowledge and understanding of patients regarding antibiotics and whether they are effective against self-limiting conditions such as ARIs. This includes South Africa. Alongside this, concerns with a lack of understanding of terms such as AMR and the implications amongst patients and their families potentially exacerbating inappropriate prescribing and dispensing of antibiotics. Consequently, it is crucial that patients are a key element of any targeted programmes by governments, health insurance companies and others to improve future antibiotic utilisation in ambulatory care in LMICs thereby reducing AMR. We have seen especially in higher-income countries that patients are generally more aware that coughs, influenza-like symptoms and colds are caused by viruses, and that antibiotics should only be prescribed where needed, including for bacterial and not for viral infections. However, there can still be challenges with their knowledge and understanding, along with the implications of AMR.

There are a number of ongoing initiatives in South Africa to improve the utilisation of antibiotics in ambulatory care given ongoing concerns, thereby seeking to reduce AMR. These are summarised in Chigome et al. and Sono et al., and centre around the National AMR Strategy Framework for 2017-2024. Despite specific legislation regarding the dispensing of prescription-only medicines in South Africa, there is evidence that the purchasing of antibiotics without a prescription does take place in the country. However, this is variable depending on the pharmacy type, location and patient characteristics.

As a result of ongoing concerns in South Africa regarding AMR, as well as variable findings regarding current rates of purchasing of antibiotics without a prescription in the country, there is a need to explore these issues further. This includes patient behaviour and their knowledge regarding antibiotics and AMR, building on earlier studies. The first step includes ascertaining current rates of purchasing of antibiotics without a prescription in South Africa, and the rationale for this action, given variable findings including knowledge of antibiotics and AMR amongst pharmacists and their assistants.

The second step is to gain a greater understanding of the extent and rationale why patients seek antibiotics without a prescription in South Africa from community pharmacies. Along with this, their understanding of key aspects of antibiotics and AMR given a current paucity of such knowledge in South Africa. As stated in our previous publication, we chose a rural province in South Africa for this study since there are typically extended travelling distances for patients to healthcare facilities and long waiting times to see a healthcare professional (HCP), including for self-limiting conditions such as ARIs, with resultant resource implications. These circumstances could lead to patients putting pressure on pharmacists and pharmacists’ assistants in community pharmacies to dispense antibiotics without a prescription, exacerbated by concerns with their knowledge of antibiotics and AMR.

Our approach was to initially undertake a small-scale preliminary pilot study with a structured questionnaire amongst patients as they leave community pharmacies as proof of concept. This is seen as important since we were already aware that a questionnaire survey amongst community pharmacists and their assistants may underestimate the extent of dispensing of antibiotics without a prescription in LMICs. As before, the concept is to investigate the feasibility of administering the proposed questionnaire amongst patients as they leave community pharmacies. At the same time, seeking to minimise implementation challenges brought about by these circumstances before embarking on the main study. Coupled with this, seek to understand the experiences and views of patients regarding the relevance of the questions being asked and their understanding of these questions. In addition, seek to ascertain the time taken to interview patients with the questionnaire, which is an important factor to consider for busy patients on side-walks. The findings of the pilot study, including suggestions from patients, will enhance the validity of the main study through amending the questionnaire and data collection process as required. In view of this, we report on the findings of the pilot study and the subsequent implications for the final data collection instrument and process in this paper.

AMR: Antimicrobial resistance

**Methods**

**Study approach and setting**

A descriptive approach was employed for this pilot study, which built on the successful pilot study we conducted recently amongst pharmacists and their assistants in the same province using a self-administered questionnaire. Consequently, the current study was conducted without making any changes to the research environment. As a result, the patients were approached from some of the same pharmacies where pharmacists and their assistants took part in the pilot study. Both pharmacy types, i.e. chain and independent pharmacies, were important for this pilot study as we observed in the previous pilot study that pharmacists from chain pharmacies were reluctant to participate in the study. In addition, community pharmacists and their assistants may underestimate the extent of dispensing antibiotics without a prescription in self-administered questionnaires due to fear of sanctions and beliefs of more appropriate prescribing and dispensing behaviour than observed in reality. Consequently, for this pilot study, six community pharmacies in the same province (three independent and three chain pharmacies), all...
within a 45 km radius from each other, were selected based on convenience and/or being part of previous the pilot study. For this pilot study, we used a two-step approach. Step 1 involved initial interviews with a limited number of patients, who were exiting community pharmacies using an interviewer-administered questionnaire. Step 2 involved cognitive interviews with the same patients to evaluate their comprehension of the survey questions and terminology used, as well as to seek their suggestions on potential adaptations to the questionnaire for the main study.

Data from the interviewer-administered questionnaires were entered into a Microsoft Excel® spreadsheet and summarised descriptively, using frequencies and percentages.

**Patient questionnaire**

The patient questionnaire was developed drawing from existing literature.[27,42,56,57] In view of concerns regarding the length of the questionnaire, which we observed in our experience with the community pharmacists and their assistants, we divided the patient questionnaire into two parts, each with its own objectives. As far as possible, closed-ended questions or statements were provided with suitable response options to assist with timely completion.

The objectives of the first part of the questionnaire (Part 1) were to (i) determine the extent of purchasing antibiotics without a prescription amongst both chain and independent pharmacies; and (ii) understand the rationale for this activity, including the condition/problem for which antibiotics were purchased. The second part of the questionnaire (Part 2) sought to evaluate patients’ knowledge of key aspects of antibiotics and AMR current concerns.

The initial questionnaire, including Part 1 and Part 2, was reviewed by the co-authors based on their considerable experience in this area across LMICs and subsequently adapted before the pilot study [Supplementary Tables 1 and 2]. We have used this approach before when developing questionnaires where no standardised questionnaire was available.[50,56-60] The questionnaire was exclusively provided in English due to concerns related to the lack of standardised terminology across the different languages used in South Africa, which could potentially impact the reliability and consistency of the research instrument. However, during data collection, explanations were provided in the relevant native language when necessary.

**Enrolment and data collection**

For the purpose of the pilot study, the aim was to administer each part of the questionnaire to between 8 and 10 patients. Two different sets of patients would be interviewed for Part 1 and Part 2, respectively. This was done deliberately to be able to fully undertake the cognitive interviews with each participating patient after completion of the questionnaire and not be rushed.

Patients who came out of the pharmacies holding medication bags were approached and invited to participate in a pilot study. Those who indicated their willingness to participate were given more information about the study and requested to provide written informed consent before the start of the interview. Participation was completely voluntary, and patients were informed that they could withdraw from the study at any time without providing reasons for their withdrawal.

All interviews were conducted by the lead author (TMS), with responses recorded manually on the questionnaire for both Parts 1 and 2. Interviews took place outside the pharmacies in a convenient semi-private area such as where benches or chairs were available in the vicinity of the pharmacy.

**Follow-up cognitive interviews**

For each participant, on completion of the interviewer-administered questionnaire, a cognitive interview was conducted by TMS. This interview was started by asking the participants what they generally thought about the questionnaire. This was followed by going through each question with the patient and asking them for possible areas to improve the questionnaire if pertinent. More in-depth questioning was used where it was perceived that patients had difficulty understanding a question, or had misunderstood it when answering. All patient responses were manually noted on an extra sheet of paper and the responses collated.

**Ethical approval**

Ethical approval for the study was obtained from the Sefako Makgatho University Research Ethics Committee (MUREC/P/229/2023:PG). Permission to conduct the study from the National Department of Health was not required, as no public sector facilities were included in this study. The pilot study only commenced after ethical clearance was received. All patient responses remained confidential and data are stored securely in a password-protected computer with access to TMS only. Data will be discarded minimum 5 after publication of the results years, according to institutional policies.

**Results**

**Summary of questionnaire responses from patients**

Overall, 11 patients were approached for an interview to complete Part 1 of the questionnaire. Two patients from chain pharmacies were in a hurry and consequently declined participation. One patient exiting from an independent pharmacy also declined participation stating they were not interested in the study. For Part 2 of the questionnaire, 10 patients were approached. One patient exiting from a chain pharmacy and one from an independent pharmacy said they were in a hurry, and consequently could not participate.

Eight patients eventually participated in the interview to complete Part 1 of the questionnaire, with the same number but different patients participating in the interview to complete Part 2 of the questionnaire. Patient characteristics including the extent of medicines and antibiotics dispensed are summarised in Table 2.
The average time taken to administer Part 1 of the questionnaire was 1 min and 47 s, and for Part 2 this was 2 min and 39 s.

Table 3 contains feedback on the nature of antibiotics dispensed to the five patients interviewed with Part 1 of the questionnaire, whether these were dispensed without a prescription or not, and the rationale for this activity. Three of the five patients being dispensed an antibiotic were dispensed an antibiotic without a prescription. All three patients were exiting from an independent pharmacy. No patient exiting from a chain pharmacy was dispensed an antibiotic without a prescription in this pilot study.

There was mixed knowledge regarding antibiotics and AMR amongst the eight patients interviewed with Part 2 of the questionnaire [Table 4].

Responses to the cognitive interviews
Part 1 of the questionnaire
Out of 8 participating patients, 6 demonstrated a satisfactory understanding of the questionnaire, indicating that the questions were generally clear and well-formulated. One patient suggested including an option to indicate completion of ABET (adult education certificate for those who did not finish high school) as an additional category under the education level. Another patient recommended expanding the scope of the questionnaire beyond antibiotics to include all medications. However, this is outside of the scope of the current study.

Participants typically indicated the need to receive instructions regarding how to use, store and discard antibiotics. This though is also outside the scope of the current study. Alongside this, participants generally emphasised the importance of assessing patients’ understanding of how to take antibiotics and why they were being prescribed or dispensed in the first place. This underscores the relevance of evaluating patients’ comprehension of their prescribed treatment when discussed or dispensed to gain insights into their decision-making process relating to the purchasing of antibiotics without a prescription.

*Correct or ideal response to knowledge question/statement

not contribute significantly to the study findings especially if Question 12 is rephrased.

Part 2 of the questionnaire

Amongst the eight participants, three expressed difficulties with understanding the concept of AMR and openly admitted to guessing their response to the first question. In addition, another participant expressed confusion regarding the term ‘resistant.’ As a result, this participant did not comprehend how germs can exhibit resistance [Question 2, Table 4], mistakenly believing it is antibiotics themselves that possess resistance. This participant also suggested adding HCPs including dentists and pharmacists to Question 10 [Table 4]; however, this is outside the scope of this study. It is possible that a pharmacist could facilitate obtaining a prescription from a doctor without the patient seeing the doctor, as this participant directly visits the pharmacy when she falls ill.

Regarding Question 12 [Table 4], one participant indicated that the community cannot be concerned about something they are unaware of. Consequently, it was proposed to rephrase the question to highlight that the community should be concerned about AMR. This participant also perceived the responsibility for proper antibiotic use rests solely with HCPs [Question 13, Table 4], and this should be taken into account when considering future modifications to the question-wording.

Furthermore, another participant suggested including the following statements:
- I am knowledgeable on how to take my antibiotics
- I have been informed on how to take my antibiotics
- I have been provided with explanations for the reasons behind taking my antibiotics.

Consequently, overall recommendations to the Part 2 of the pilot study version of the questionnaire [Supplementary Table S2] included the following:
- Revising the wording of Question 1 to enhance clarity and ensure that participants grasp the concept of AMR. Potentially, utilise layman’s terms and possibly include a brief explanation to aid comprehension
- Clarifying the language in Question 2 to avoid semantic misunderstandings
- Providing concise definitions or explanations when administering the questionnaire to ensure participants correctly interpret the terms used in the question
- Adjust the wording of Question 12 to highlight the significance of community awareness and concern regarding AMR. Ensure the question encourages participants to reflect on the broader community perspective
- Refining the wording of Question 13 to account for the diverse perspectives on the responsibility for antibiotic use, including both HCPs and the general public
- Integrate the suggested statements into the first questionnaire, possibly as additional items to gauge participants’ knowledge and awareness regarding antibiotic use and its associated information.

Updated questionnaire

Table 5 (Part 1) and Table 6 (Part 2) contain the updated questionnaire for inclusion in the main study following feedback from the pilot study participants (Part 1 and 2) [Supplementary Tables 1 and 2] and experience in administering the questionnaire in an interview.

Discussion and Next Steps

Overall, there was appreciable utilisation of antibiotics amongst the surveyed patients (62.8% in Part 1) reflecting the importance of seeking ways to improve future utilisation to reduce AMR in South Africa.

From our small pilot study, the purchasing of antibiotics without a prescription seems to be higher compared to Anstey Watkins et al. and Do et al.,[22,53] but similar to the findings of Mokwele et al. amongst independent pharmacies.[54] However,
the findings of this pilot study resonated with the conclusions of Mokwele et al. in that no antibiotics were dispensed without a prescription in franchised (chain) pharmacies.\(^{54}\) Having said this, the number of patients in this pilot study was small.

The reasons for patients requesting antibiotics without a prescription [Table 3] were similar to previous studies [Table 1]. These included economic reasons and circumstances as well as no time to take off work to see a HCP.

Our pilot study suggests that patients report a higher prevalence of antibiotic dispensing without a prescription when asked directly compared to feedback from pharmacists and their assistants.\(^{52}\) This is similar to the findings when using simulated patients versus questionnaires with pharmacists, justifying our approach.\(^{55,61}\) Nevertheless, the sample sizes in both pilot studies are too small to draw definitive conclusions, with further investigation is needed before drawing any firm conclusions.

The first part of the questionnaire proved effective in documenting antibiotic purchasing without a prescription, patient demographics and reasons behind the behaviour. Nonetheless, we received feedback for questionnaire improvement, and these suggestions have been integrated into an updated questionnaire [Table 5].
There were more concerns with the second part of the questionnaire in terms of understanding amongst participants. Language plays a crucial role in interviews with patients on AMS in South Africa due to the country’s diverse linguistic landscape. South Africa has 11 official languages, and it is essential to consider the linguistic diversity of the country when conducting interviews on AMS to ensure that the questions are understood by all respondents. The language in the questionnaire has been updated following the feedback ready for the main study [Table 6], and the researchers administering the revised questionnaire in the main study will be aware of these issues when asking the questions.

It was feasible to undertake both questionnaires in a rapid time to fully engage with patients throughout the survey, which is encouraging. As a result, justifying the initial rationale to divide the questionnaire into two, with each part having different objectives. However, given a combined interview length of not more than 5 min to administer both questionnaires, these can potentially be combined for the main study without compromising the findings. This approach would potentially increase the number of participants in this rural setting [Tables 5 and 6] and will be undertaken in the main study where feasible.

The next phase of our study will involve conducting the main study with pharmacists and their assistants across this rural province using the updated questionnaire.[12] The findings from this study with pharmacists and their assistants will subsequently be used to determine the number of patients needed for the patient questionnaire study. This will be based on the likely percentage of patients being dispensed antibiotics without a prescription in this rural province, bearing in mind the feedback from pharmacists and their assistants is likely to be a conservative estimate.

**Conclusion**

Similar to the pilot study amongst pharmacists and their assistants in rural South Africa, this pilot study raised considerable concerns regarding the extent of purchasing antibiotics without a prescription. There was also a concern regarding the knowledge of whether antibiotics can treat colds and coughs, as well as knowledge of AMR amongst patients. These issues will be explored further in the main study to provide future direction to the authorities as the Government in South Africa seeks to improve antibiotic utilisation and reduce AMR in line with the goals of the NAP.
