FIRST CROSS-CORRELATION ANALYSIS OF L1 AND A1 DATA TAKEN BETWEEN
CORRELATED ENVIRONMENTAL NOISE \[24\]. THIS PAPER DESCRIBES
DISTINGUISH CORRELATIONS DUE TO A SGWB FROM THOSE DUE TO
STREAMS TO STOCHASTIC GWS AND THUS PROVIDING A MEANS TO
ROTATED, CHANGING THE RESPONSE OF THE CORRELATED DATA
AROUND 900 Hz. IN ADDITION, THE ALLEGRO BAR CAN BE
CLOSEST PAIR AMONG MODERN GROUND-BASED GW DETECTOR
DETECTORS [20] AND ALSO USING TWO OR MORE KILOMETER-SCALE
SEARCHES HAVE BEEN PERFORMED USING TWO RESONANT-BAR DE-
TECTORS [26].

I. INTRODUCTION

One of the signals targeted by the current generation of ground-based gravitational-wave (GW) detectors is a stochastic gravitational-wave background (SGWB) \([1–3]\). Such a background is analogous to the cosmic microwave background, although the dominant contribution is unlikely to have a blackbody spectrum. A SGWB can be characterized as cosmological or astrophysical in origin. Cosmological backgrounds can arise from, for example, pre-big-bang models \([4–6]\), amplification of quantum vacuum fluctuations during inflation \([7–9]\), phase transitions \([10,11]\), and cosmic strings \([12–14]\). Astrophysical backgrounds consist of a superposition of unresolved sources, which can include rotating neutron stars \([15,16]\), supernovae \([17]\), and low-mass x-ray binaries \([18]\).

The standard cross-correlation search \([19]\) for a SGWB necessarily requires two or more GW detectors. Such searches have been performed using two resonant-bar detectors \([20]\) and also using two or more kilometer-scale GW interferometers (IFOs) \([21–23]\). The present work describes the results of the first cross-correlation analysis carried out between an IFO [the 4 km IFO at the LIGO Livingston Observatory (LLO), known as L1] and a bar (the cryogenic ALLEGRO detector, referred to as A1). This pair of detectors is separated by only 40 km, the closest pair among modern ground-based GW detector sites, which allows it to probe the stochastic GW spectrum around 900 Hz. In addition, the ALLEGRO bar can be rotated, changing the response of the correlated data streams to stochastic GWs and thus providing a means to distinguish correlations due to a SGWB from those due to correlated environmental noise \([24]\). This paper describes cross-correlation analysis of L1 and A1 data taken between February 22 and March 23, 2005, during LIGO’s fourth science run (S4). Average sensitivities of L1 and A1 during S4 are shown in Fig. 1. ALLEGRO was operated in three orientations, which modulated the GW response of the LLO-ALLEGRO pair through 180° of phase.

The LLO-ALLEGRO correlation experiment is complementary to experiments using data from the two LIGO sites, in that it is sensitive to a SGWB at frequencies of around 900 Hz rather than 100 Hz. Targeted sources are thus those with a relatively narrow-band spectrum peaked near 900 Hz. Spectra with such shapes can arise from...

FIG. 1. Sensitivity of the LLO IFO (L1) and the ALLEGRO bar (A1) during S4, along with strain associated with \(\Omega_{\text{gw}}(f) = 1.02\) (assuming a Hubble constant of \(H_0 = 72 \text{ km/s/Mpc}\)). [There are two \(\Omega_{\text{gw}}(f) = 1.02\) curves, corresponding to the different strain levels such a background would generate in an IFO and a bar, as explained in Sec. II and \([26]\).] The quantity plotted is amplitude spectral density (ASD), the square root of the one-sided power spectral density defined in (4.2), at a resolution of 0.25 Hz.
exotic cosmological models, as described in Sec. II, or from astrophysical populations [16].

The organization of this paper is as follows. Section II reviews the properties and characterization of a SGWB. Section III describes the LLO and ALLEGRO experimental arrangements, including the data acquisition and strain calibration for each instrument. Section IV describes the cross-correlation method and its application to the present situation. Section V describes the details of the post-processing methods and statistical interpretation of the cross-correlation results. Section VI describes the results of the cross-correlation measurement and the corresponding upper limit on the SGWB strength in the range 850–950 Hz. Section VII describes the results of our analysis within the analysis software and in the hardware of the pipeline when applied to simulated signals injected both within the analysis software and in the hardware of the instruments themselves. Section VIII compares our results to those of previous experiments and to the sensitivities of other operating detector pairs. Section IX considers the prospects for future work.

II. STOCHASTIC GRAVITATIONAL-WAVE BACKGROUNDS

A gravitational wave (GW) is described by the metric tensor perturbation \( h_{ab}(\mathbf{r}, t) \). A given GW detector, located at position \( \mathbf{r}_{\text{det}} \) on the Earth, will measure a GW strain which, in the long-wavelength limit, is some projection of this tensor:

\[
h(t) = h_{ab}(\mathbf{r}_{\text{det}}, t)d^{ab}, \tag{2.1}
\]

where \( d^{ab} \) is the detector response tensor, which is

\[
d^{ab}_{\text{(ifo)}} = \frac{1}{2}(\mathbf{x}^a \mathbf{x}^b - \mathbf{\hat{n}}^a \mathbf{\hat{n}}^b) \tag{2.2}
\]

for an interferometer with arms parallel to the unit vectors \( \mathbf{x} \) and \( \mathbf{\hat{n}} \) and

\[
d^{ab}_{\text{(bar)}} = \mathbf{\hat{u}}^a \mathbf{\hat{u}}^b \tag{2.3}
\]

for a resonant bar with long axis parallel to the unit vector \( \mathbf{\hat{u}} \).

A stochastic GW background (SGWB) can arise from a superposition of uncorrelated cosmological or astrophysical sources. Such a background, which we assume to be isotropic, unpolarized, stationary, and Gaussian, will generate a cross correlation between the strains measured by two detectors. In terms of the continuous Fourier transform defined by \( \tilde{a}(f) = \int_{-\infty}^{\infty} dt \, a(t) \exp(-i2\pi ft) \), the expected cross correlation is

\[
\langle \tilde{h}_1^*(f) \tilde{h}_2(f) \rangle = \frac{1}{2}(f - f')S_{gw}(f)\gamma_{12}(f), \tag{2.4}
\]

where

\[
\gamma_{12}(f) = d_{1ab}d^1_{cd} \frac{5}{4\pi} \int d^2\Omega_p \, P_{TT}^{hab} \int d^2\Omega \, e^{i2\pi f(h_2 - h_1)/c} \tag{2.5}
\]
is the overlap reduction function (ORF) [25] between the two detectors, defined in terms of the projector \( P_{TT}^{hab,cd} \) onto traceless symmetric tensors transverse to the unit vector \( \mathbf{\hat{n}} \). The ORF for several detector pairs of interest is shown in Fig. 2.

\( S_{gw}(f) \) is the one-sided spectrum of the SGWB. This is the one-sided power spectral density (PSD) the background would generate in an interferometer with perpendicular arms, which can be seen from (2.4) and the fact that the ORF of such an interferometer with itself is unity. Since the ORF of a resonant bar with itself is \( 4/3 \) (see [26] and Sec. VII A for more details), the PSD of the strain measured by a bar detector due to the SGWB would be \( (4/3)S_{gw}(f) \).

A related measure of the spectrum is the dimensionless quantity \( \Omega_{gw}(f) \), the GW energy density per unit logarithmic frequency divided by the critical energy density \( \rho_c \) needed to close the universe:

\[
\Omega_{gw}(f) = \frac{f \, d\rho_{gw}}{df} = \frac{10\pi^2}{3H_0^2} f^3 S_{gw}(f). \tag{2.6}
\]

Note that the definition \( \Omega_{gw}(f) \) thus depends on the value

FIG. 2. The overlap reduction function for LIGO Livingston Observatory (LLO) with ALLEGRO and with LIGO Hanford Observatory (LHO). The three LLO-ALLEGRO curves correspond to the three orientations in which ALLEGRO was operated during LIGO’s S4 run: “XARM” (N108°W) is nearly parallel to the x-arm of LLO (“aligned”); “YARM” (N18°W) is nearly parallel to the y-arm of LLO (“antialigned”); NULL (N63°W) is halfway in between these two orientations (a “null alignment” midway between the two LLO arms). Note that for nonzero frequencies, the separation vector between the two sites breaks the symmetry between the XARM and YARM alignments, and leads to an offset of the NULL curve, as described in [26]. The LLO-LHO overlap reduction function is shown for reference. The frequency band of the present analysis, 850 Hz \( \leq f \leq 950 \) Hz, is indicated with dashed vertical lines.
of the Hubble constant $H_0$. Most SGWB literature avoids this artificial uncertainty by working in terms of

$$h_{100}^2 \Omega_{gw}(f) = \left( \frac{H_0}{100 \text{ km/s/Mpc}} \right)^2 \Omega_{gw}(f)$$

(2.7)

rather than $\Omega_{gw}(f)$ itself. We will instead follow the precedent set by [22] and quote numerical values for $\Omega_{gw}(f)$ assuming a Hubble constant of 72 km/s/Mpc.

A variety of spectral shapes have been proposed for $\Omega_{gw}$, for both astrophysical and cosmological stochastic backgrounds [3,27,28]. For example, whereas the slow-roll inflationary model predicts a constant $\Omega_{gw}(f)$ in the bands of LIGO or ALLEGRO, certain alternative cosmological models predict broken-power-law spectra, where the rising and falling slopes and the peak frequency are determined by model parameters [3]. String-inspired pre-big-bang cosmological models belong to this category [5,29]. For certain ranges of these three parameters, the LLO-ALLEGRO correlation measurement offers the best constraints on theory that can be inferred from any contemporary observation. This can happen, e.g., if the power-law exponent on the rising spectral slope is greater than 3 and the peak frequency is sufficiently close to 900 Hz [30].

### III. EXPERIMENTAL SETUP

#### A. The LIGO Livingston interferometer

The experimental setup of the LIGO observatories has been described at length elsewhere [31]. Here we provide a brief review, with particular attention paid to details significant for the LLO-ALLEGRO cross-correlation measurement.

The LIGO Livingston Observatory (LLO) is an interferometric GW detector with perpendicular 4-km arms. The laser interferometer senses directly any changes in the differential arm length. It does this by splitting a light beam at the vertex, sending the separate beams into 4-km long optical cavities of their respective arms, and then recombining the beams to detect any change in the optical phase difference between the arms, which is equivalent to a difference in light travel time. This provides a measurement of $h(t)$ as defined in (2.1) and (2.2). However, the measured quantity is not exactly $h(t)$ for two reasons.

First, there are local forces which perturb the test masses, and so produce changes in arm length. There are also optical and electronic fluctuations that mimic real strains. The combination of these effects causes a strain noise $n(t)$ to always be present in the output, producing a measurement of

$$s(t) = h(t) + n(t).$$

(3.1)

Second, the test masses are not really free. There is a servo system, which uses changes in the differential arm length as its error signal $q(t)$, and then applies extra (“control”) forces to the test masses to keep the differential arm length nearly zero. It is this error signal $q(t)$ which is recorded, and its relationship to the strain estimate $s(t)$ is most easily described in the Fourier domain:

$$\tilde{s}(f) = \tilde{R}(f)\tilde{q}(f).$$

(3.2)

The response function $\tilde{R}(f)$ is estimated by a combination of modeling and measurement [32] and varies slowly over the course of the experiment.

Because the error signal $q(t)$ has a smaller dynamic range than the reconstructed strain $s(t)$, our analysis starts from the digitized time series $q[k] = q(t_k)$ (sampled $2^{14}$ times per second, and digitally downsampled to 4096 Hz in the analysis) and reconstructs the LLO strain only in the frequency domain.

#### B. The ALLEGRO resonant-bar detector

The ALLEGRO resonant detector, operated by a group from Louisiana State University [33], is a two-ton aluminum cylinder coupled to a niobium secondary resonator. The secondary resonator is part of an inductive transducer [34] which is coupled to a DC SQUID. Strain along the cylindrical axis excites the first longitudinal vibrational mode of the bar. The transducer is tuned for sensitivity to this mechanical mode. Raw data acquired from the detector thus reflect the high-$Q$ resonant mechanical response of the system. A major technical challenge of this analysis is due to the extent to which the bar data differ from those of the interferometer.

1. **Data acquisition, heterodyning, and sampling**

The ALLEGRO detector has a relatively narrow sensitive band of $\sim 100$ Hz centered around $\sim 900$ Hz near the two normal modes of the mechanical bar-resonator system. For this reason, the output of the detector can first be heterodyned with a commercial lock-in amplifier to greatly reduce the sampling rate, which is set at 250 samples/s. Both the in-phase and quadrature outputs of the lock-in are recorded and the detector output can thus be represented as a complex time series which covers a 250 Hz band centered on the lock-in reference oscillator frequency. This reference frequency is chosen to be near the center of the sensitive band, and during the S4 run it was set to 904 Hz. The overall timing of data heterodyned in this fashion is provided by both the sampling clock and the reference oscillator. Both time bases were locked to the Global Positioning System (GPS) time reference.

The nature of the resonant detector and its data acquisition system gives rise to a number of timing issues: heterodyning, filter delays of the electronics, and the timing of the data acquisition system itself [35]. It is of critical importance that the timing be fully understood so that the phase of any potential signal may be recovered. Convincing evidence that all of the issues are accounted for is demonstrated by the recovery and cross correlation of test signals simultaneously injected into both detectors.
2. Strain calibration

The raw detector output is proportional to the displacement of the secondary resonator, and thus has a spectrum with sharp line features due to the high-$Q$ resonances of the bar-resonator system as can be seen in Fig. 3. The desired GW signal is the effective strain on the bar, and recovering this means undoing the resonant response of the detector. This response has a long coherence time—thus long stretches of data are needed to resolve the narrow lines in the raw data. The strain data have a much flatter spectrum, as shown in Fig. 1. Therefore it is practical to generate the calibrated strain time series, $s(t)$, and use that as the input to the cross-correlation analysis.

The calibration procedure, described in detail in [35], is carried out in the frequency domain and consists of the following: A 30 min stretch of clean ALLEGRO data is windowed and Fourier transformed. The mechanical mode frequencies drift slightly due to small temperature variations, so these frequencies are determined for each stretch and those are incorporated into the model of the mechanical response of the system to a strain. The model consists of two double poles at these normal mode frequencies. In addition to this response, we must then account for the phase shifts due to the time delays in the lock-in and antialiasing filters.

After applying the full response function, the data are then inverse Fourier transformed back to the time domain. The next 50% overlapping 30 min segment is then taken. The windowed segments are stitched together until the entire continuous stretch of good data is completed. The first and last 15 minutes are dropped. The result represents a heterodyned complex time series of strain, whose amplitude spectral density is shown in Fig. 1.

The overall scale of the detector output in terms of strain is determined by applying a known signal to the bar. A force applied to one end of the bar has a simple theoretical relationship to an equivalent gravitational strain [35–37]. A calibrated force can be applied via a capacitive “force generator” which also provides the mechanism used for hardware signal injections. A reciprocal measurement—excitation followed by measurement with the same transducer—along with known properties of the mechanical system, allows the determination of the force generator constant. With that constant determined (with units of newtons per volt), a calibrated force is applied to the bar and the overall scale of the response determined.

3. Orientation

A unique feature of this experiment is the ability to rotate the ALLEGRO detector and modulate the response of the ALLEGRO-LLO pair to a GW background [24]. Data were taken in three different orientations of ALLEGRO, known as XARM, YARM, and NULL, detailed in Table I. As shown in Fig. 2 and (2.4), these
orientations correspond to different pair responses due to different overlap reduction functions. In the XARM orientation—the bar axis parallel to the x-arm of the interferometer—a GW signal produces positive correlation between the data in the two detectors. In the YARM orientation a GW signal produces an anticorrelation. In the NULL orientation—the bar aligned halfway between the two arms of the interferometer—the pair has very nearly zero sensitivity as a GW signal produces almost zero correlation between the detectors’ data. A real signal is thus modulated whereas many types of instrumental correlation would not have the same dependence on orientation.

IV. CROSS-CORRELATION METHOD

This section describes the method to used to search for a SGWB by cross-correlating detector outputs. In the case of L1-A1 correlation measurements, it is complicated by the different sampling rates for the two instruments and the fact that the A1 data are heterodyned at 904 Hz prior to digitization.

A. Continuous-time idealization

Both ground-based interferometric and resonant-mass detectors produce a time-series output which can be related to a discrete sampling of the signal

\[ s_i(t) = h_i(t) + n_i(t), \]

where \( i \) labels the detector (1 or 2 in this case), \( h_i(t) \) is the gravitational-wave strain defined in (2.1), and \( n_i(t) \) is the instrumental noise associated with each detector, converted into an equivalent strain. The detector output is characterized by its power spectral density \( P_i(f) \),

\[ \langle s_i^2(f)s_i^*(f') \rangle = \frac{1}{2} \delta(f - f') P_i(f), \]

which should be dominated by the autocorrelation of the noise \( \{s_i^2(f)\} = \langle h_i^2(f)h_i^*(f') \rangle \). If the instrument noise is approximately uncorrelated, the expected cross correlation of the detector outputs is [cf. (2.4)]

\[ \langle s_1^*(f)s_2(f') \rangle = \langle h_1^*(f)h_2(f') \rangle = \frac{1}{2} \delta(f - f') S_{gw}(f) \gamma_{12}(f), \]

which can be used along with the autocorrelation (4.2) to determine the statistical properties of the cross-correlation statistic defined below.

We use the optimally filtered cross-correlation method described in [19,21] to calculate a cross-correlation statistic which is an approximation to the continuous-time cross-correlation statistic

\[ Y_c = \int dt_1 dt_2 s_1(t_1) Q(t_1 - t_2) s_2(t_2) \]

\[ = \int df \tilde{s}_1^*(f) \tilde{Q}(f) \tilde{s}_2(f). \]

In the continuous-time idealization, such a cross-correlation statistic, calculated over a time \( T \), has an expected mean

\[ \mu_{Y_c} = \langle Y_c \rangle = \frac{T}{2} \int_{-\infty}^{\infty} df \gamma(|f|) S_{gw}(f) \tilde{Q}(f) \]

and variance

\[ \sigma_{Y_c}^2 = \langle (Y_c - \mu_{Y_c})^2 \rangle = \frac{T}{4} \int_{-\infty}^{\infty} df P_1(f)P_2(f) |\tilde{Q}(f)|^2. \]

Using (4.5) and (4.6), the optimal choice for the filter \( \tilde{Q}(f) \), given a predicted shape for the spectrum \( S_{gw}(f) \) can be shown [19] to be

\[ \tilde{Q}(f) \approx \frac{\gamma(|f|) S_{gw}(f)}{P_1(f)P_2(f)}. \]

If the spectrum of gravitational waves is assumed to be a power law over the frequency band of interest, a convenient parametrization of the spectrum, in terms of \( \Omega_{gw}(f) \) defined in (2.6), is

\[ \Omega_{gw}(f) = \Omega_R \left( \frac{f}{f_R} \right)^{\alpha}, \]

where \( f_R \) us a conveniently chosen reference frequency and \( \Omega_R = \Omega_{gw}(f_R) \). The cross-correlation measurement is then a measurement of \( \Omega_R \), and if the optimal filter is normalized according to

\[ \tilde{Q}(f) = \frac{\gamma(f)}{[f^3 P_1(f)P_2(f)]^{1/2}}, \]

then the expected statistics of \( Y_c \) in the presence of a background of actual strength \( \Omega_R \) are

\[ \mu_{Y_c} = \Omega_R T \]

and

\[ \sigma_{Y_c}^2 = T \left( \frac{10\pi^2}{3H_0^2} \right)^2 \int_{-\infty}^{\infty} \left[ \frac{\gamma(f)}{f^3 P_1(f)P_2(f)} \right]^{2} |\tilde{Q}(f)|^2 \]

and a measurement of \( Y_c/T \) provides a point estimate of the background strength \( \Omega_R \) with associated estimated error bar \( \sigma_{Y_c}/T \).

B. Discrete-time method

1. Handling of different sampling rates and heterodyning

Stochastic-background measurements using pairs of LIGO interferometers [21] have implemented (4.4) from discrete samplings \( s[k] = s(t_0 + k\delta t) \) as follows: First the continuous Fourier transforms \( \tilde{s}(f) \) were approximated...
using the discrete Fourier transforms of windowed and zero-padded versions of the discrete time series; then an optimal filter was constructed using an approximation to (4.7), and finally the product of the three was summed bin-by-bin to approximate the integral over frequencies. The discrete version of $\hat{Q}(f)$ was simplified in two ways: first, because of the averaging used in calculating the power spectrum, the frequency resolution on the optimal filter was generally coarser than that associated with the discrete Fourier transforms of the data streams, and second, the value of the optimal filter was arbitrarily set to zero outside some desired range of frequencies $f_{\text{min}} \leq f \leq f_{\text{max}}$. This was justified because the optimal filter tended to have little support for frequencies outside that range.

The present experiment has two additional complications associated with the discretization of the time-series data. First, the A1 data are not a simple time sampling of the gravitational-wave strain, but are base banded with a heterodyning frequency $f_2^h = 904$ Hz as described in Sec. III B 1 and III B 2. Second, the A1 data are sampled at $(\delta t_2)^{-1} = 250$ Hz, while the L1 data are sampled at 16384 Hz, and subsequently downsampled to $(\delta t_1)^{-1} = 4096$ Hz. This would make a time domain cross correlation extremely problematic, as it would necessitate a large variety of time offsets $t_1 - t_2$. In the frequency domain, it means that the downsampled L1 data, once calibrated, represent frequencies ranging from $-2048$ Hz to $2048$ Hz, while the calibrated A1 data represent frequencies ranging from $(904 - 125)$ Hz to $(904 + 125)$ Hz, $250$ Hz. These different frequency ranges do not pose a problem, as long as the range of frequencies chosen for the integral satisfies $f_{\text{min}} > 779$ Hz and $f_{\text{max}} < 1029$ Hz. Another requirement is that, for the chosen frequency resolution, the A1 data heterodyne reference frequency must align with a frequency bin in the L1 data. This is satisfied for integer-second data spans and integer-hertz reference frequencies. With these conditions, the Fourier transforms of the A1 and L1 data are both defined over a common set of frequencies, as detailed in [38]. Looking at the A1 spectrum in Fig. 1, a reasonable range of frequencies should be a subset of the range 850 Hz $\leq f \leq 950$ Hz.

2. Discrete-time cross correlation

Explicitly, the time series inputs to the analysis pipeline, from each $T = 60$ sec of analyzed data, are:

(i) For L1, a real time series $\{q_{1}[j]\}_{j = 0, \ldots, N_{1} - 1}$, sampled at $(\delta t_1)^{-1} = 4096$ Hz, consisting of $N_{1} = T/\delta t_1 = 245,760$ points. This is obtained by down-sampling the raw data stream by a factor of 4. The data are downsampled to 4096 Hz rather than 2048 Hz to ensure that the roll-off of the associated antialiasing filter is outside the frequency range being analyzed. The raw L1 data are related to gravitational-wave strain by the calibration response function $\tilde{R}_1(f)$ constructed as described in Sec. III A.

(ii) For A1, a complex time series $\{s_{1}[k]\}_{k = 0, \ldots, N_{2} - 1}$, sampled at $(\delta t_2)^{-1} = 250$ Hz, consisting of $N_{2} = T/\delta t_2 = 150,000$ points. This is calibrated to represent strain data as described in Sec. III B 2, but still heterodyned.

To produce an approximation of the Fourier transform of the data from detector $i$, the data are multiplied by an appropriate windowing function, zero padded to twice their original length, discrete-Fourier-transformed, and multiplied by $\delta t_i$. In addition, the L1 data are multiplied by a calibration response function, while the A1 data are interpreted as representing frequencies appropriate in light of the heterodyne. For L1,

$$\tilde{s}_1(f) \sim \tilde{s}_1[i] := \tilde{R}_1(f_i) \sum_{j=0}^{N_{1}-1} w_1[j]q_1[j] \times \exp\left(-\frac{i2\pi f j}{2N_1}\right) \delta t_1,$$

$$\ell = -N_1, \ldots, N_1 - 1,$$  \hspace{1cm} (4.12)

where $f_i = k_0 T$ is the frequency associated with the $t$th frequency bin. In the case of A1, the identification is offset by $l_{2}^{h} = f_h \cdot (2T) = 107,880$:

$$\tilde{s}_2(f) \sim \tilde{s}_2[i] := \sum_{k=0}^{N_{2}-1} w_2[k]q_2[k] \times \exp\left(-\frac{i2\pi f - \ell_{2}^{h} k}{2N_2}\right) \delta t_2,$$

$$\ell = \ell_{2}^{h} - N_2, \ldots, \ell_{2}^{h} + N_2 - 1.$$  \hspace{1cm} (4.13)

As is shown in [38], if we construct a cross-correlation statistic

$$Y := \sum_{\ell=\ell_{\text{min}}}^{\ell_{\text{max}}} \frac{1}{2T} [\tilde{s}_1(f_{\ell})]^* \tilde{Q}(f_{\ell}) \tilde{s}_2(f_{\ell}),$$  \hspace{1cm} (4.14)

the expected mean value in the presence of a stochastic background with spectrum $S_g(f)$ is

$$\mu := \langle Y \rangle = \frac{1}{w_1 w_2} \sum_{\ell=\ell_{\text{min}}}^{\ell_{\text{max}}} \frac{1}{2T} [\tilde{Q}(f_{\ell})] y(f_{\ell}) S_g(f_{\ell}).$$  \hspace{1cm} (4.15)

where $w_1 w_2$ is an average of the product of the two windows, calculated using the points which exist at both sampling rates; specifically, if $r_1$ and $r_2$ are the smallest integers such that $\delta t_1/\delta t_2 = r_1/r_2 = 125/2048$,

$$w_1 w_2 = \frac{r_1 r_2}{N} \sum_{n=0}^{N_{1}/(r_1 r_2) - 1} w_1[n r_1] w_2[n r_2].$$  \hspace{1cm} (4.16)

Note that, while the average value given by (4.15) is manifestly real, any particular measurement of $Y$ will be
The optimal filter slide through the data to remain adjacent. This method is known as "sliding power spectrum estimation" because, as we analyze successive segments of data, the segments used to calculate the PSDs for the optimal filter slide through the data to remain adjacent. The $\delta f = 0.25$ Hz resolution is obtained by calculating the power spectra using Welch’s method with 29 overlapped 4-second subsegments in each 60-second segment of data, for a total of 58 subsegments.

$$\sigma^2 := \frac{1}{2} \langle Y^* Y \rangle$$

$$= T \frac{2}{8 w_1^2 w_2^2} \sum_{\ell=-w}^{w} \frac{1}{2T} \langle \tilde{Q}(f_\ell) \rangle^2 P_1(|f_\ell|) P_2(|f_\ell|), \quad (4.17)$$

where once again $w_1^2 w_2^2$ is an average over the time samples the two windows have “in common”:

$$w_1^2 w_2^2 = \frac{f_1 f_2}{N} \sum_{n=0}^N (w_1[nr_2])^2 (w_2[nr_1])^2. \quad (4.18)$$

3. Construction of the optimal filter

To perform the cross correlation in (4.14), we need to construct an optimal filter by a discrete approximation to (4.9). We approximate the power spectra $P(f)$ using Welch’s method [39]; as a consequence of the averaging of periodograms constructed from shorter stretches of data, the power spectra are estimated with a frequency resolution $\delta f$ which is coarser than the $1/2T$ associated with the construction in (4.14). As detailed in [21], we handle this by first multiplying together $\tilde{s}(f_\ell)$ and $\tilde{s}(f_\ell)$ at the finer frequency resolution, then summing together sets of $2T \delta f$ bins and multiplying them by the coarser-grained optimal filter. For our search, $\delta f = 0.25$ Hz and $T = 60$ sec, so $2T \delta f = 30$.

4. Power spectrum estimation

Because the noise power spectrum of the LLO can vary with time, we continuously update the optimal filter used in the cross-correlation measurement. However, using an optimal filter constructed from power spectra calculated from the same data to be analyzed leads to a bias in the cross-correlation statistic $Y$, as detailed in [40]. To avoid this, we analyze each $T = 60$ sec segment of data using an optimal filter constructed from the average of the power spectra from the segments before and after the segment to be analyzed. This method is known as “sliding power spectrum estimation” because, as we analyze successive segments of data, the segments used to calculate the PSDs for the optimal filter slide through the data to remain adjacent. The $\delta f = 0.25$ Hz resolution is obtained by calculating the power spectra using Welch’s method with 29 overlapped 4-second subsegments in each 60-second segment of data, for a total of 58 subsegments.

$$Y^{opt} = \frac{\sum \sigma_i^{-2} Y_i}{\sum \sigma_i^{-2}}. \quad (5.1a)$$

$$\sigma^{opt} = \left( \sum \sigma_i^{-2} \right)^{-1/2}. \quad (5.1b)$$
To minimize spectral leakage, we use Hann windows in our analysis segments, which would reduce the effective observing time by approximately one-half, so we overlap the segments by 50% to make full use of as much data as possible. This introduces correlations between overlapping data segments, which modifies the optimal combination slightly, as detailed in [41].

D. Statistical interpretation

The end result of the analysis and postprocessing of a set of data is an optimally combined complex cross-correlation statistic \( Y^{\text{opt}} \) with a theoretical mean of \( \hat{\Omega}_R T \) and an associated standard deviation of \( \sigma_{Y^{\text{opt}}} \) on both the real and imaginary parts. We can construct from this our overall point estimate on the unknown actual value of \( \hat{\Omega}_R \) and the corresponding one-sigma error bar:

\[
\hat{\Omega}_R = \frac{Y^{\text{opt}}}{T} \quad \sigma_{\Omega} = \frac{\sigma_{Y^{\text{opt}}}}{T}.
\]

(5.2a)

(5.2b)

For a given value of \( \hat{\Omega}_R \), and assuming \( \sigma_\Omega \) to be given, the likelihood function for the complex point estimate to have a particular value \( \hat{\Omega}_R = x + iy \) is

\[
P(x, y|\hat{\Omega}_R, \sigma_\Omega) = \frac{d^2 P}{dxdy} = \frac{1}{2\pi\sigma_\Omega^2} \exp\left(\frac{-|x + iy - \hat{\Omega}_R|^2}{2\sigma_\Omega^2}\right) = \frac{1}{2\pi\sigma_\Omega^2} e^{-|x + iy - \hat{\Omega}_R|^2/2\sigma_\Omega^2}.
\]

(5.3)

Given a prior probability density function on \( \hat{\Omega}_R \), Bayes’s theorem allows us to construct a posterior

\[
P(\hat{\Omega}_R|x, y, \sigma_\Omega) = \frac{P(x, y|\hat{\Omega}_R, \sigma_\Omega)P(\hat{\Omega}_R)}{P(x, y|\sigma_\Omega)} \propto e^{-|x - \hat{\Omega}_R|^2/2\sigma_\Omega^2} P(\hat{\Omega}_R).
\]

(5.4)

where \( x = \Re \hat{\Omega}_R \). In this work we choose a uniform prior over the interval \([0, \Omega_{\text{max}}]\), where \( \Omega_{\text{max}} \) is chosen to be 116 (the previous best upper limit at frequencies around 900 Hz [20]), except in the case of the hardware injections in Sec. VII C, where the \textit{a priori} upper limit is taken to be well above the level of the injection.

Given a posterior probability density function (PDF), the 90% confidence level Bayesian upper limit \( \Omega_{\text{UL}} \) is defined by

\[
\int_{0}^{\Omega_{\text{UL}}} d\Omega_R P(\Omega_R|x, y, \sigma_\Omega) = 0.90.
\]

(5.5)

Alternatively, any range containing 90% of the area under the posterior PDF can be thought of as a Bayesian 90% confidence level range. To allow consistent handling of results with and without simulated signals, we choose the narrowest range which represents 90% of the area under the posterior PDF. (This is the range whose PDF values are larger than all those outside the range.) For a low enough signal-to-noise ratio \( \Re \hat{\Omega}_R/\sigma_\Omega \), this range is from 0 to \( \Omega_{\text{UL}} \).

E. Treatment of calibration uncertainty

In reality, the conversion of raw data from the LIGO and ALLEGRO GW detectors into GW strain is not perfect. We model this uncertainty in the calibration process as a time- and frequency-independent phase and magnitude correction, so that \( \hat{\Omega}_R = x + iy \) and \( \sigma_\Omega \) are actually related to \( \hat{\Omega}_R e^{\Lambda + i\phi} \), where \( \Lambda \) and \( \phi \) are unknown amplitude and phase corrections; the likelihood function then becomes

\[
P(x, y|\hat{\Omega}_R, \sigma_\Omega, \Lambda, \phi) = \frac{1}{2\pi\sigma_\Omega^2} \times \exp\left(-\frac{|x + iy - \hat{\Omega}_R e^{\Lambda + i\phi}|^2}{2\sigma_\Omega^2}\right).
\]

(5.6)

Given a prior PDF \( P(\Lambda, \phi) \) for the calibration corrections, we can marginalize over these nuisance parameters and obtain a marginalized likelihood function

\[
P(x, y|\hat{\Omega}_R, \sigma_\Omega) = \int_{-\infty}^{\infty} d\Lambda \int_{-\pi}^{\pi} d\phi P(x, y|\hat{\Omega}_R, \sigma_\Omega, \Lambda, \phi)P(\Lambda, \phi).
\]

(5.7)

We take this prior PDF to be Gaussian in \( \Lambda \) and \( \phi \), with a standard deviation added in quadrature from the quoted amplitude and phase uncertainty for the two instruments. For L1, this is 5% in amplitude and 2\(^\circ\) in phase [32] and for A1 it is 10% in amplitude and 3\(^\circ\) in phase [35].

VI. ANALYSIS OF COINCIDENT DATA

A. Determination of analysis parameters

To avoid biasing our results, we set aside approximately 9% of the data, spread throughout the run, as a \textit{playground} on which to tune our analysis parameters. Based on playground investigations, we settled on the following parameters for our analysis:

(i) Overlapping 60-second Hann-windowed analysis segments

(ii) Frequency range 850 Hz \( \leq f \leq 950 \) Hz, 0.25 Hz resolution for optimal filter

(iii) L1 data downsampled to 4096 Hz before analysis

(iv) Removal of the following frequencies from the optimal filter: 900 Hz (2.25 Hz wide), 904 Hz (0.25 Hz wide).

The frequencies to remove were chosen on the basis of studies of the coherence of stretches of L1 and A1 data (see Fig. 4); 900 Hz is the only harmonic of the 60 Hz power line within our analysis band, and detectable coherence is

022001-10
seen for frequencies within 1 Hz of the line. 904 Hz is notched out because, as the heterodyne frequency, it corresponds to DC in the heterodyned A1 data. After completing the cross-correlation analysis, we computed the coherence from the full run of data, as shown in Fig. 5. The results are similar to those from the playground, except for a lower background level, and a feature at the heterodyning frequency.

The relevant range of frequencies can be determined by looking at the support of the integrand of (4.11), known as the sensitivity integrand. The overall sensitivity integrand, constructed as a weighted average over all the nonplayground data used in the analysis, is plotted in Fig. 6. The area under this curve for a range of frequencies is proportional to that frequency range’s contribution to $\sigma^{-2}$. We see that the integrand does indeed become negligible by a frequency of 850 Hz on the lower end and 950 Hz on the upper end. We further see that most of the sensitivity comes from a 20-Hz wide band centered around 915 Hz.

**B. Cross correlation and upper limit results**

After data quality cuts, exclusion of the “playground,” and application of the stationarity cut described in Sec. VA, 44 806 one-minute segments of data were analyzed, for an effective observing time of 384.1 hours (considering the effects of Hann windowing), of which 181.2 hours was in the XARM orientation, 114.7 in the YARM orientation, and 88.2 in the NULL orientation. The
The results in Table II include the ORF describing the geometry in the optimal filter. This means an orientation-independent non-GW cross correlation present in the data would change sign between XARM and YARM, and would also suppressed at other frequencies corresponding to lines in the A1 noise power spectrum.

The results in Table II include the ORF describing the geometry in the optimal filter. This means an orientation-independent non-GW cross correlation present in the data would change sign between XARM and YARM, and would dominate the final result. Note also that, because the optimal filter includes the ORF, the relative orientation of LLO and ALLEGRO is already included in these results. This is reflected, for example, in the large error bars on the NULL result.

TABLE II. Results of optimally filtered cross correlation of non-playground data. Results are shown for data in each of three orientations (XARM, YARM, and NULL). Additionally, the XARM and YARM results are combined with the optimal weighting (proportional to one over the square of the error bar) to give a “non-NUL” result, and results from all three orientations are optimally combined to give an overall result. In each case, \( T_{eff} \) is the effective observing time including the effects of overlapping Hann windows. Note that, since the non-NUL data are much more sensitive than the NULL data, they dominate the final result. Note also that, because the optimal filter includes the ORF, the relative orientation of LLO and ALLEGRO is already included in these results. This is reflected, for example, in the large error bars on the NULL result.

FIG. 6. The sensitivity integrand for the data used in the cross-correlation analysis, normalized so its integral equals unity. The area under this curve, between two frequencies, is the fractional contribution to \( \sigma^{-2} \) from that range of frequencies. Notice that the nine frequency bins masked out around 900 Hz and the one at 904 Hz give no contribution, and that the sensitivity integrand is also suppressed at other frequencies corresponding to lines in the A1 noise power spectrum.

The results in Table II include the ORF describing the geometry in the optimal filter. This means an orientation-independent non-GW cross correlation present in the data would change sign between XARM and YARM, and would dominate the final result. Note also that, because the optimal filter includes the ORF, the relative orientation of LLO and ALLEGRO is already included in these results. This is reflected, for example, in the large error bars on the NULL result.

TABLE III. The cross-correlation results of Table II, scaled by \( \gamma(915 \text{ Hz}) \) from Table I, the value of the ORF at the frequency of peak sensitivity. This gives a sense of the “raw” cross correlation, independent of the orientation-dependent geometrical factor. The different observing times explain the remaining variation in the one-sigma error bar for the measurement, which should be inversely proportional to the square root of the observing time.

look much larger in the NULL result. One way to remove the effects of the observing geometry and compare orientation-independent cross correlations is to remove the \( \gamma(f) \) from (4.9). Since the ORF for each orientation is nearly constant across the observing band, and notably across the region of peak sensitivity, it is sufficient to multiply the overall results in each case by \( \gamma(915 \text{ Hz}) \). This is shown in Table III, where we again see no significant cross-correlation, and sensitivities whose relative sizes are well explained by the differing observing times.

We use the methods of Secs. V D and V E to construct a posterior PDF from the overall cross-correlation measurement of \( 0.31 + 0.30i \) and estimated error bar of 0.48, taking into consideration the nominal calibration uncertainty of 11% in magnitude and 3.6° in phase to obtain the posterior PDF shown in Fig. 7. The narrowest 90%-likely

FIG. 7. Posterior probability density function associated with the overall combined point estimate of \( 0.31 + 0.30i \) and estimated error bar of 0.48, considering the uncertainty in the phase and amplitude of the calibration. The shaded region represents 90% of the area under the curve, leading to an upper limit on \( \Omega_R \) of 1.02, which corresponds to a gravitational-wave strain of \( 1.5 \times 10^{-23} \text{ Hz}^{-1/2} \) at the peak frequency of 915 Hz.
VII. VALIDATION VIA SIGNAL INJECTION

To check the effectiveness of our algorithm at detecting stochastic GW signals, we performed our search on data with simulated waveforms “injected” into them. This was done both by introducing the simulated signals into the analysis pipeline (software injections), and by physically driving both instruments in coincidence (hardware injections). Hardware injections provide an end-to-end test of our detection pipeline (software injections), and by physically injecting constant

\[ S_{gw}(915 \text{ Hz}) (1.5 \times 10^{-23} \text{ Hz}^{-1/2})^2. \]

Then, the second pair can be expressed as

\[
\tilde{h}_1(f) = \frac{S_{gw}(f)}{2}\sqrt{\gamma_{11}(a(f)z_1(f) + b(f)z_2(f))} \quad (7.4a)
\]

\[
\tilde{h}_2(f) = \frac{S_{gw}(f)}{2}\sqrt{\gamma_{22}(b(f)z_1(f) + a(f)z_2(f))}. \quad (7.4b)
\]

where \( a = \sqrt{(1 + s)/2} \) and \( b = \gamma_{12}/\sqrt{2(1 + s)} \gamma_{11}\gamma_{22} \) are determined completely by the three ORFs. Either pair of simulated strains obeys (7.2). The signals for software injections were generated using (7.4); those for hardware injections were generated by an older code which used (7.3). Further details of simulated signal generation are in [42].

B. Results of software simulation

We performed software injections into the full S4 coincident playground, 4316 overlapping one-minute analysis segments with an effective observing time of 37.0 hours considering the effects of Hann windows (16.7 hours of this is in the XARM orientation, 11.2 hours in the YARM orientation, and 9.0 hours in the NULL orientation). We injected constant-\(\Omega_{gw}(f)\) spectra of strengths corresponding to \(\Omega_R = 1.9, 3.9, 9.6, \) and 19, as well as a test with the SGWB amplitude set to 0 to reproduce the analysis of the playground itself. Note that even the strongest of these injections does not produce correlations detectable in an individual one-minute analysis segment. The results are summarized in Table IV. In each case, the actual injected value of \(\Omega_R\) is consistent with the real part of the point estimate to within the one-sigma estimated error bar; the imaginary part of the point estimate remains zero to within the error bar. The results for injections at \(\Omega_R = 1.9\) and stronger would correspond to statistical “detections” at the 90% or better confidence level.

C. Results of hardware injection

During S4, a set of simulated signals was injected in the hardware of ALLEGRO and LLO. These injections served to test the full detection pipeline as well as the calibrations of both instruments. As described in detail in [42], the preparation of simulated waveforms for hardware injec-

TABLE V. Results of hardware injections. Simulated waveforms with an effective signal strength of \( \Omega_{gw}(f) = 8100 \) were injected coincidentally in the ALLEGRO and the LIGO Livingston (LLO) detectors. The A and B sets of injections took place during the XARM and NULL observing times, respectively. Independent of the actual orientation, the simulated signals were generated and analyzed assuming different orientations: Y ARM, NULL, and XARM orientations were assumed for the injections labeled minus, null, and plus, respectively. The first pair of columns shows the error bars and point estimates scaled by \( \gamma(915 \text{ Hz}) \) to give a raw cross correlation as in Table III. (Note that the null alignment represents not-quite-perfect misalignment, as noted in Table I [\( \gamma(915 \text{ Hz}) = 0.03 \) rather than zero], the injection still leads to a statistically significant cross correlation even in the null orientation.) Note that the error bars, thus scaled, are comparable for all six injections, while the level of correlation or anticorrelation depends on the orientation associated with the injection being analyzed. The subsequent columns relate to the standard cross-correlation statistic, with the ORF included in the optimal filter, so the relative insensitivity in the null alignment is reflected in large error bars, while the point estimates are all positive and in the vicinity of the injected value of 8100. All point estimates given include corrections for known phase offsets associated with the injection system. The row labeled “all” gives the optimally weighted combination of all six results. The point estimates and one-sigma estimated error bars were combined to give 90% confidence ranges with and without marginalization over calibration uncertainty, mimicking the statistical analysis described in Secs. V D and V E.

</table>

The results show some variation of magnitude and phase of the point estimates, especially for the null injections. However, all the injection results are consistent with the injected signal strength within statistical and systematic uncertainties. This is illustrated informally in Fig. 8, which shows the point estimates on the complex plane, each surrounded by an error circle of radius 2.15 times the corresponding estimated error bar. (This radius was chosen because 90% of the volume under a two-dimensional Gaussian falls within a circle of radius 2.15\( \sigma \).) Those circles all overlap with a region centered at the actual injection strength illustrating the magnitude and phase uncertainty in the calibration. The systematic error can be more quantitatively evaluated using the method of Sec. V E to produce a posterior PDF associated with each injection measurement. This is illustrated for the optimally combined point estimate of \( 7448 + 65i \) and associated estimated error bar 47 in Fig. 9, and ranges corresponding to the most likely 90% confidence range under the posterior PDFs (with and without marginalization) are included in Table V. For each of the six injections, as well as for the combined result, the actual injected value of 8100 falls into the range after marginalization over the calibration uncertainty.

VIII. COMPARISON TO OTHER EXPERIMENTS

The previous most sensitive direct upper limit at the frequencies probed by this experiment was set by cross correlating the outputs of the Explorer and Nautilus resonant-bar detectors [20]. They found an upper limit on \( h_{100}^2 \Omega_{gw}(907.20 \text{ Hz}) \) of 60. Using the value of 72 km/s/Mpc for the Hubble constant, that translates to a limit of 116 on \( \Omega_{gw}(907.20 \text{ Hz}) \), upon which our limit of 1.02 is a hundredfold improvement.

Data from LLO, taken during S4, were also correlated with data from the LIGO Hanford Observatory (LHO) to set an upper limit on \( \Omega_{gw}(f) \) at frequencies between 50 Hz and 150 Hz [23]. Correlations between LLO and LHO are not suited to measurements at high frequencies because of the effects of the ORF, illustrated in Fig. 2. For comparison, rough measurements using S4 LLO-LHO data and a band from 850 Hz to 950 Hz yield upper limits of around 20, while those confined to 905 Hz \( \leq f \leq 925 \text{ Hz} \) (the band
Correlations between the 4 km and 2 km IFOs at LHO, known as H1 and H2, respectively, are not suppressed by the ORF, which is identically unity for colocated, coaligned IFOs. Since H1 and L1 have comparable sensitivities, the most significant factor in comparing H1-H2 to L1-A1 sensitivity is the relative sensitivities of A1 and H2. Since H2 was about a factor of 50 (in power) more sensitive than A1 during S4, averaged across the band from 905 Hz to 925 Hz, we would expect an H1-H2 correlation measurement during S4 to be a factor of 7 or better more sensitive than L1-A1 as a measure of 10^{-10} gw/10^{-3} f/10^{-4} gw. However, the fact that H1 and H2 share the same physical environment at LHO necessitates a careful consideration of correlated noise which is ongoing [43].

Work is also currently under way to search for a SGWB at frequencies around 900 Hz by correlating data from the Virgo IFO with the resonant-bar detectors Auriga, Explorer, and Nautilus [44].

Finally, an indirect limit can be set on SGWB strength due to the energy density in the associated gravitational waves themselves, which is given by

$$\rho_{gw} = \rho_{crit} \int_0^\infty \frac{\Omega_{gw}(f)}{f} df. \quad (8.1)$$

The most stringent limit is on a cosmological SGWB, set by the success of big-bang nucleosynthesis, is $\rho_{gw}/\rho_{crit} \leq 1.1 \times 10^{-5}$ [3]. In comparison, a background of the strength constrained by our measurement, $\Omega_R = 1.02$, would contribute about $2 \times 10^{-2}$ to $\rho_{gw}/\rho_{crit}$, if it were confined to the most sensitive region between 905 Hz and 925 Hz. (Spread over the full range of integration 850 Hz \(\leq f \leq 950 \) Hz, it would contribute $1 \times 10^{-1}$.)
Note, however, that this nucleosynthesis bound is not relevant for a SGWB of astrophysical origin.

IX. FUTURE PROSPECTS

LIGO’s S5 science run began in November 5, 2005, with the aim of collecting 1 yr of coincident data at LIGO design sensitivity. ALLEGRO has also been in operation over that time period, so the measurement documented in this paper could be repeated with S5 data. Such a measurement would be more sensitive due to L1’s roughly fivefold reduction in strain noise power at 900 Hz between S4 and S5, and because of the larger volume of data (roughly 20 times as much). Those two improvements could combine to lead to an improvement of about an order of magnitude in \( \Omega_{gw} \) sensitivity. However, no immediate plans exist to carry out an analysis with S5 data, because this incremental quantitative improvement in sensitivity would still leave us far from the level needed to detect a cosmological background consistent with the nucleosynthesis bound, or an astrophysical background arising from a realistic model.

Additionally, the greater sensitivity of the H1-H2 pair means that a background detectable with L1-A1 would first be seen in H1-H2. In the event that a “surprise” correlation is seen in H1-H2 which cannot be attributed to noise, correlation measurements such as LLO-ALLEGRO and Virgo-AURIGA could be useful for confirming or ruling out a gravitational origin.

X. CONCLUSIONS

We have reported the results of the first truly heterogeneous cross-correlation measurement to search for a stochastic gravitational-wave background. While the upper limit of \( 1.5 \times 10^{-23} \text{ Hz}^{-1/2} \) on the strain of the SGWB corresponds to a hundredfold improvement over the previous direct upper limit on \( \Omega_{gw}(f) \) in this frequency band [20], the amplitude of conceivable spectral shapes is already constrained more strongly by results at other frequencies [22,23]. The lasting legacy of this work is thus more likely the overcoming of technical challenges of cross-correlating data streams from instruments with significantly different characteristics. Most obviously, we performed a coherent analysis of data from resonant-mass and interferometric data, but additionally the data were sampled at different rates, ALLEGRO data were heterodyned and therefore complex in the time domain, and entirely different methods were used for the calibrations of both instruments. Lessons learned from this analysis will be valuable not only for possible collaborations between future generations of detectors of different types, but also between interferometers operated by different collaborations.
